## Abstract

Nowadays, rammed earth construction is attracting renewed interest throughout the world thanks to its "green" characteristics in the context of sustainable development. Firstly, using a local material (soil on site or near the site), rammed earth constructions have very low embodied energy. Secondly, rammed earth houses have an attractive appearance and present advantageous living comfort due to substantial thermal inertia and the "natural regulator of moisture" of rammed earth walls. This is why several research studies have been carried out recently to study the mechanical and thermal characteristics of rammed earth. However, to our knowledge, there are not yet sufficient studies on the tensile strength and the shear strength of rammed earth. The tensile strength of rammed earth is neglected in general due to its very low value, but in extreme conditions (e.g., seismic conditions), knowing the tensile strength is necessary for structural design. Moreover, the shear strength is required in many cases to check the local failure of rammed earth quickly, which has been observed in old structures (especially those submitted to concentrated loads).

This paper presents experimental results on tensile strengths and the Poisson ratio of rammed earth specimens. Local failure tests were also conducted on 1 m × 1 m × 0.3 m wallettes manufactured in the laboratory. The shear strength was then identified using a simple method based on compressive strength, tensile strength and Mohr's circle theory. The approach proposed was validated by tests on the wallettes. Finite Element (FE) modeling was also carried out to confirm the results. Last, the method presented was validated for stabilized rammed earth lintels presented in the literature.

*Keywords: rammed earth, tensile strength, shear strength, failure.*

## 30 **1 Introduction**

31 Rammed earth materials are ideally sandy-clayey gravels. The materials are prepared to their optimum  
32 moisture content and compacted inside a temporary formwork to form walls. The earth composition varies  
33 greatly and always contains clay but should not include any organic components. Clay acts as the binder  
34 between the grains, a mixture of silt, sand, and gravel up to a few centimeters in diameter. Compaction is  
35 undertaken on material prepared to its optimum moisture that provides the highest dry density for the given  
36 compactive energy (Bui *et al.* 2009b). The rammed earth wall is composed of several layers of earth. The  
37 earth is poured loose in layers about 10–15 cm thick into a timber or metal formwork, which is then rammed  
38 with a rammer (manual or pneumatic). After compaction, the thickness of each layer is typically 6–10 cm.  
39 The procedure is repeated until completion of the wall. A detailed presentation of rammed earth construction  
40 can be found in Walker *et al.* (2005).

41 For traditional rammed earth construction, referred to as “rammed earth” (RE) or “unstabilized rammed  
42 earth,” the only binder is clay. Other binders can also be added such as cement or hydraulic or calcium lime,  
43 were added. This is often called “stabilized rammed earth” (SRE). The main advantage of stabilization is the  
44 increase in durability and mechanical performance. However, stabilization increases the construction cost  
45 and environmental impact.

46 Rammed earth is the focus of scientific research for two main reasons. Firstly, in the context of sustainable  
47 building, the modern interest in earth as a building material is largely derived from its low embodied energy,  
48 both for unstabilized rammed earth (Morel *et al.* 2001) and stabilized rammed earth (Reddy and Kumar  
49 2010), and also because the material has good natural moisture buffering from indoor environments  
50 (Allinson and Hall 2010). Secondly, the heritage of rammed earth buildings in Europe and the world is still  
51 important (Fodde 2009, Bui *et al.* 2009a). Maintaining this heritage needs scientific knowledge to assess  
52 appropriate renovations.

53 Several research studies have recently been conducted to study the characteristics of rammed earth:  
54 durability and sensitivity to water (Bui *et al.* 2009a, Hall and Djerbib 2004a), thermal properties (Taylor et  
55 al. 2008, Taylor and Luther 2004), living comfort (Paul and Taylor 2008), mechanical characteristics in  
56 compression (Bui *et al.* 2009b, Bui and Morel 2009, Maniatidis and Walker 2008, Hall and Djerbib 2004b,  
57 Jaquin *et al.* 2009); pullout strength (Walker *et al.* 2001), and dynamic characteristics (Bui *et al.* 2011).

58 However, there are not yet sufficient studies on the tensile strength and the shear strength of rammed earth  
 59 (Cheah *et al.* 2012). The tensile strength of rammed earth is neglected in general due to its very low value,  
 60 but in extreme conditions (e.g. seismic), knowing tensile strength is necessary for the structural design  
 61 (Gomes *et al.* 2011). Shear strength is also required in many cases to check the punching strength of rammed  
 62 earth walls quickly (Fig. 1), such as beams directly placed on a rammed earth wall (roof beams, lintel beams;  
 63 Ciancio and Robinson 2011) and vertical ties in anti-seismic devices (Hamilton *et al.* 2006).  
 64 This paper presents the experimental results on tensile strengths and the Poisson ratio of rammed earth. The  
 65 shear strength is also identified using a simple method based on compressive strength, tensile strength, and  
 66 Mohr's circle theory. The approach proposed was then validated by the tests on the (1 m × 1 m × 0.3 m)  
 67 walls manufactured in the laboratory. FE modeling taking account the non-linear behavior of RE material  
 68 was also conducted. The material studied in this paper is unstabilised rammed earth but the presented method  
 69 is also applicable in the case of stabilized rammed earth.

70  
 71 **Figure 1: Typical failure of an old rammed earth wall in France.**

72 **2 Manufacture of specimens**

73 **2.1 Soils**

74 Three different soils were used in this study (Table 1). These soils were taken directly from the RE building  
 75 sites. The soils have the clay contents convenient for RE manufacture (5–10%, Walker *et al.* 2005).

76 **Table 1: Soils used in this study**

Soil	Clay (by weight)	Silt	Sand	Gravel
A	10%	25%	18%	47%
B	5%	30%	49%	16%
C	8%	34%	8%	50%

77

## 78 **2.2 Different types of specimen**

79 The representativeness of specimens manufactured in laboratory was discussed in a previous study (Bui *et al.*  
80 2009b). In the present study, to identify several parameters that are useful for numerical and analytical  
81 models that will be presented in this paper, several tests in both directions with several types of specimen are  
82 necessary: cylindrical specimens for tests determining the Poisson ratio and the tensile strength within  
83 earthen layers (Brazilian test), prismatic specimens for compression tests, and wallettes for tests identifying  
84 the behavior and failure mode of RE walls under concentrated loading. The choice of each type of specimen  
85 will be explained in the corresponding section.

## 86 **2.3 Cylindrical specimen manufacturing**

87 To determine the tensile strength using the Brazilian test and measure the Poisson ratio, cylindrical  
88 specimens were needed. Extensometers were used on prismatic specimens without success because a square  
89 section did not enable homogeneous movements of the elastic wires that connected the extensometers (for  
90 greater detail, see section 3.1)

91 The automatic Proctor machine was adopted (Figure 2). The standard mold of the Proctor test was replaced  
92 by a mold 16 cm in diameter and 32 cm high. To obtain the dry density of *in-situ* rammed earth material  
93 ( $\sim 1920 \text{ kg/m}^3$ ; Bui *et al.* 2009b), a series of preliminary tests were conducted to determine the manufacturing  
94 water content and the amount of soil to be poured into the mold for each layer. An 11% moisture content was  
95 chosen as the compaction moisture content and 2.2 kg of moist soil was weighed out for each layer. Each  
96 layer received the Proctor energy ( $E = 0.6 \text{ kJ/dm}^3$ ). There were six compaction layers in each specimen  
97 prepared. The final height of the cylinder after the release was about 30 cm. Prior to mixing, the soil was  
98 sieved through a 2-cm screen.

99

100  
101 **Figure 2: Automatic Proctor machine and modified mold.**  
102

103 After the compaction process, the specimens were removed from the mould. The bottom surface of the  
104 cylinder, since it was in contact with the bottom side of the mold during compaction, was smooth and did not  
105 require any further treatment before strength testing. However, the more uneven upper surface was capped  
106 with a mortar (2 lime: 3 sand by weight) to provide a flat smooth surface parallel with the bottom side.  
107 During drying, the specimen was left in the ambient atmosphere.

#### 108 **2.4 Manufacture of prismatic specimens**

109 To ensure a faithful representation of the in-situ wall material, the manufacturing mode and material used for  
110 laboratory specimens should be as identical as possible to those used for the rammed earth houses. Therefore  
111 the earth was taken from the construction site of a rammed earth house (soil B). The manufacturing water  
112 content and the compaction energy in the laboratory were the same as on site. The manufacturing water  
113 content was about 10%.

114 The dimensions of specimens tested in the direction perpendicular to the layers were 40cm x 40cm x 70cm,  
115 with nine layers (Bui *et al.* 2009a). The specimens tested in the direction parallel to the layers were  
116 composed of only three layers. The specimen dimensions are 40 cm × 40 cm and roughly 20 cm high. The  
117 last layer is given special attention during compaction to obtain a surface that is as flat as possible. To  
118 achieve a slenderness ratio of 2, the specimens are then cut with a table saw. Three specimens measuring (40  
119 × 40 × 20) cm<sup>3</sup> were manufactured, which provided six specimens (20 × 20 × 40) cm<sup>3</sup> for testing in the  
120 parallel direction. Since the specimen is tested in the direction parallel to the layers, surfacing is not  
121 necessary, because the two surfaces that were in contact with the formwork are sufficiently flat.

122 A section formwork measuring 40×40 cm<sup>2</sup> was chosen for the following reasons: a larger section makes it  
123 impossible to put specimens on the press to test in the direction perpendicular to the layers. In addition, a

124 smaller cross-section makes it impossible to manufacture representative specimens tested in the direction  
125 parallel with the layers. Indeed, for compression tests in the direction parallel to the layers, the specimen  
126 must have at least three layers because the last layer is less compacted and consequently less representative  
127 (Bui and Morel 2009). Therefore, the specimen had to measure at least 20 cm for each side. More details on  
128 the manufacture of representative specimens can be found in Bui *et al.* (2009a).

## 129 **2.5 Manufacture of wallettes**

130 In order to study the general behavior of RE walls and especially the walls subjected to concentrated loads,  
131 two walls measuring  $(100 \times 100 \times 30) \text{ cm}^3$  were made with soil C. The thickness of each layer after  
132 compaction was 14–15 cm. Surfacing was provided by a layer of mortar.

## 133 **3 Characterization on “small” specimens**

### 134 **3.1 Compression in the direction perpendicular to layers**

135 The cylindrical specimens with 16cm diameter and 30cm height were tested in compression between two  
136 hardened steel plates. Three cylinders were tested for each series. To measure service strains, extensometers  
137 were placed in the central half of the cylinders to minimize end effects on measured performance. To  
138 determine the Poisson ratio, lateral strain measurements, as well as vertical measurements, were taken.  
139 Figure 3 shows the configuration of a uniaxial compression strength test: extensometers measured the  
140 longitudinal strains and LVDT sensors measured lateral displacements, which helps calculate the lateral  
141 strains.

142 For each test, three extensometers and three LVDT sensors, fixed at an interval of  $120^\circ$  on the radial plan,  
143 were used to verify the repeatability of the results. An extensometer measures the strain between two points:  
144 one point at the center of a layer and the other point at the center of the upper layer. The distance between  
145 two points of the extensometer is 6.2 cm, while the thickness of a layer of the specimen is about 5 cm. The  
146 cylinders were loaded by displacement control at a constant rate of 0.1 mm/min until failure.

147 For the soil C specimens (wallette soil), the compressive strength, the Young modulus and the Poisson's  
148 ratio measured were  $1.9 \pm 0.2 \text{ MPa}$ ,  $500 \pm 40 \text{ MPa}$ , and  $0.22 \pm 0.01$ , respectively. The results of other  
149 specimens will be presented in the following section. More information about the characterization on  
150 cylindrical specimens can be found in Bui *et al.* (2013).

**Figure 3: Set-up to measure the Poisson ratio.**

### **3.2 Compression in the direction parallel to layers**

The compression tests in the parallel direction of the layers were *a priori* done a nonhomogenous material (Fig. 4a). Firstly, the stress was not uniform in the specimen during the test due to the heterogeneity of the dry density within a layer (which increased from the bottom to the up of layer). So the stress was discontinuous from one layer to another. Therefore, the determined stress was an average value (the load applied by the press divided by the section of the specimen). Secondly, layer separation occurred fairly early during the test, notably the first crack in the last layer, meaning that the specimen was no longer a continuous medium. However, these separations did not seem to significantly alter the specimen's mechanical capacities, since each layer continued to support the load alone. There was no change in slope even after the abrupt loss of adhesion due to the separation (Fig. 4b). During the test, the first crack appeared fairly early, due to the separation of the last manufacturing layer (Fig. 4a). This phenomenon has already been discussed in Bui and Morel (2009). The complete failure of the specimen occurred when the third vertical crack appeared. It corresponded to the maximum extension of the material (the strain corresponds to the maximal stress) and to the internal failure within a layer leading to the failure of the entire specimen. The results will be discussed in section 3.3.2 and will be used to identify tensile strength at the interfaces between layers.

180

### 181 3.3 Tensile strength

182 Since RE is a superposition of earth layers, it is necessary to distinguish two tensile strengths: the tensile  
183 strength in earth layers and the tensile strength at the interfaces of earth layers (Fig. 4a).

#### 184 3.3.1 Tensile strength within rammed earth layers

185 Within a RE layer, the mechanical behaviors are similar in the directions parallel and perpendicular to the  
186 layers (Bui and Morel 2009). Therefore, it is supposed that the tensile strengths within a layer are also  
187 similar in two directions.

188 To determinate the tensile strength within earth layers, the Brazilian test was used (Fig. 5). The synthesis of  
189 the results is illustrated in Fig. 6.

190

211

212

To apply the analytical method that will be presented in section 4.5 for stabilized rammed earth, soil A was also stabilized at 5% and 10% by cement (by weight). The results of these stabilized specimens are also presented in Fig. 6.

Figure 6 presents the experimental relationship between the compressive strength and the tensile strength within the layers of the tested specimens. From this figure, the tensile strength within layers ( $f_t$ ) can be expressed by:  $f_t = 0.11 f_c$  where  $f_c$  is the compressive strength. This expression can be simplified:  $f_t = 0.1 f_c$ .

### 3.3.2 Tensile strength at interfaces between layers

To assess the difference between the tensile strength in layers and the tensile strength at interfaces between layers (excluding the last layer), the latter was identified.

Call  $x$  and  $z$  the directions perpendicular and parallel to the layers, respectively;

$$\epsilon_{xx} = -\nu_{xx} \epsilon_{zz} = -\nu_{xx} \sigma_{zz} / E_{zz} \quad (1)$$

$$\sigma_{xx} = E_{xx} \epsilon_{xx} = -E_{xx} \nu_{xx} \sigma_{zz} / E_{zz} \quad (2)$$

Bui and Morel (2009) showed that the Young moduli in both directions were similar:  $E_{xx} \cong E_{zz}$

$$\Rightarrow \sigma_{xx} = -\nu_{xx} \sigma_{zz} \quad (3)$$

213 Following the results of tests in the direction parallel to layers, separation of the second layer was about 50%  
214 of the compressive strength in this direction ( $\sigma_{zz, \text{separation}} \cong 0.5 \sigma_{zz, \text{max}}$ ; Fig. 4b). The Poisson's ratio measured  
215 was 0.22 (more information can be found in Bui *et al.* 2013).

216 Replace these parameters in (3), it is obtained that in the direction parallel to the layers, the normal stress  
217 immediately before the separation:

$$218 \quad \Rightarrow \quad \sigma_{xx} = -0.22 \times 0.5 \sigma_{xx, \text{max}} = -0.11 f_c$$

219

220 This result shows that the tensile strength at layer interfaces (excluding the last layer) is similar to the tensile  
221 strength within the layers. Because of the layer's superposition of RE material, this result is quite surprising  
222 but shows that the assumption of an isotropic material is totally acceptable for RE. It is important to note that  
223 this result was calculated for the separation at approximately 50% (observed on the stress-strain  
224 relationship), but this separation may initiate earlier inside the specimen. Another method may be a flexural  
225 test on a RE beam, in perpendicular or parallel to the layers.

226 The result of this section is simply to evaluate the anisotropy of RE material in traction; it has no influence  
227 on the results of the following sections of this paper.

## 228 **4 Tests on the wallettes**

### 229 **4.1 Test procedure**

230 A quasi-static loading was applied by a hydraulic press (capacity, 2000 kN) on a (30×30) cm<sup>2</sup> surface at the  
231 middle of the wall (Figure 7). The wall displacements were measured using five displacement sensors  
232 (LVDT) positioned on the wall (two vertical sensors, two lateral sensors, and an out-of-plane sensor). In  
233 addition, the 3D-image-correlation technique with a stereo vision system was applied to a wallette face,  
234 making it possible to record deformations of this surface in three directions. Two 4-megapixel cameras  
235 (ALLIED Vision Technologies) were used for image acquisition. First, the investigated side was coated by a  
236 white pure hydrated lime and then black speckles were painted on this white background. The 3D  
237 displacements were measured by recording the movements of these speckles. Then the strains were  
238 calculated automatically from these displacements using Vic-3D software.

261  
262

**Figure 7: Experimentation on a wallette**

The tests were carried out 148 and 155 days after the wallettes' manufacture for the first and second wallette, respectively to assure that the wallets' water content was stable and the wallets could be considered as "dry" (Bui *et al.* 2009b). The wallettes' water content was determined after the tests and were  $1.8 \pm 0.2\%$ .

#### **4.2 Results**

Figure 8 presents the load–displacement relationships obtained for two wallettes. These two curves are similar, which shows a repeatability of results. The behavior was quasi-linear up to 42 and 45 kN, respectively, for the first and second wallettes. Then a decrease in the slope was observed, corresponding to the appearance of the first cracks in the wallettes. The mean failure load of the two wallettes reached 112 kN, which corresponds to a vertical displacement about 4.5 mm from the wallette's central point. The third phase was a post-peak behavior, which presents a substantial drop in the slope.

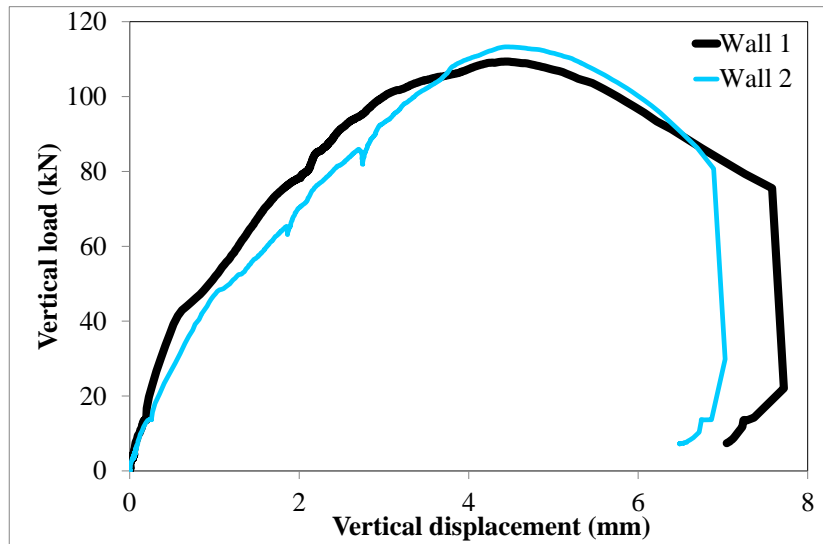

Figure 8: Load–displacement relationship of two wallettes.

263

264

265

266 Monitoring the crack propagation was recorded by the image correlation. Synchronization between the  
 267 stereovision system and the load and displacement sensors identified the behavior of the wallettes and crack  
 268 appearance (Figure 9). The cracks were identified by observing the horizontal strains  $\epsilon_{xx}$  of the wallette face.  
 269 At the beginning of the second phase (post-elastic phase, point P1 on Figure 9), a vertical crack was  
 270 observed. Then this vertical crack continued to develop and other vertical cracks appeared in the central part  
 271 (points P2 and P3 in Figure 9). When the post-peak phase began (point P4 in Figure 9), inclined cracks  
 272 appeared, which propagated to two corners of the wallette. These inclined cracks seem to have been  
 273 influenced by the friction between the wallette and the metallic base.

Figure 9: Crack development on wallette 1.

274

275

276

277 Two types of cracking were observed: vertical cracks which appeared in the central part and inclined cracks  
278 at the corners. These cracks crossed the compacted earth layers, and there was no crack bifurcation at the  
279 layer interfaces. This means that the cracks were not influenced by the layer's superposition, so the  
280 hypothesis of a homogeneous material was acceptable in this case.

281

(a)

(b)

**Figure 10: Failure modes of the wallettes: (a) Wallette 1; (b) Wallette 2.**

282

283

284

285

286 The experiment showed that the wallette zone that was under loading underwent failures and greater  
287 settlement than other zones (

288 Figure 10). A fracture surface developed between the loaded zone and the neighbor unloaded zone because  
289 of a differential settlement (Figure 11). This fracture surface was quasi-vertical and so different from those in  
290 reinforced concrete structures where the fracture was about  $45^\circ$  from the horizontal plane. In concrete  
291 constructions, several empirical formulas are proposed to determine the shear strength (Eurocode 2), which  
292 is a function of the compressive strength. For RE material, to study the behavior of a concentrated load, shear  
293 strength must also be determined.

294

295

296

297

298

299

300

301

302

**Figure 11: Fracture surface**

303 Following Mohr-Colomb theory, the shear strength is a function of cohesion, normal stress and friction  
304 angle. The material's cohesion can be quickly determined by applying the theory of Mohr's circles for  
305 compressive and tensile strengths. Following Mohr's circles and using the results presented in the first part  
306 of this paper ( $f_t=0.11f_c$ ), cohesion and friction angle were identified:  $c=0.14f_c$  and  $\varphi=51^\circ$ . This result means  
307 that for REs whose compressive strength is about 1–3 MPa, the cohesion is about 0.14–0.42 MPa. These  
308 values are coherent with the value found in the literature. Indeed, in Jaquin *et al.* (2006), a cohesion of 0.15  
309 MPa was identified for their specimens using a numerical model; in Cheah *et al.* (2012), cohesion and  
310 friction angle of stabilised rammed earth were measured that were  $45\text{-}56^\circ$  and 280-760kPa respectively.

### 311 **4.3 Discussion**

312 For old RE walls that underwent concentrated loads, vertical cracks often appeared at the boundary between  
313 the loaded zone and the unloaded zone, which resemble a fracture surface because of differential sliding.

314 The mean compressive strength of cylindrical specimens manufactured from the same soil as the wallettes  
315 was 1.9 MPa. If this strength was applied, the wallettes can resist a load of 171 kN ( $1900 \text{ kPa} \times 0.3 \text{ m} \times 0.3$   
316  $\text{m}$ ), which should overestimate the result (the experimental result was 112 kN).

317 In the experimental failure state, the maximal normal stress in the wallette was 1.22 MPa, which was the  
318 normal stress of the points under the loaded zone. It is well known in soil mechanics that away from this  
319 zone, stress decreases. If the above theoretical formula ( $v=0.14f_c$ ) was applied, the theoretical cohesion at  
320 the loaded zone was 0.17 MPa.

321 By assuming the two failure surfaces were vertical at the extremities of the loaded zone (each vertical surface  
322 was 1 m high  $\times$  0.3 m wide), the strength of the wallettes should be 124 kN. This result was close to the  
323 experimental result, which was approximately 112 kN (Table 2 2). The difference could result on one hand  
324 from the failure surface not being perfectly vertical; the angle  $\theta$  can vary from  $0^\circ$  to  $10^\circ$ . On the other hand,  
325 slenderness of the walls was greater than 2 that may induce the buckling which could decrease the  
326 experimental results.

327

328

329

330

331

**Table 2 : Comparison between the experimental and theoretical failure loads**

Experimental failure load $F_{exp}$	112 kN
Vertical compressive stress $f_c$	1.22 MPa
Theoretical cohesion ( $v_{theo} = 0.14f_c$ )	0.17 MPa
Theoretical failure load $F_{theo}$	124 kN

332

333 It is known that the representativeness of cylindrical specimens is limited (Bui *et al.* 2009b, Ciancio and  
 334 Gibbings 2012); it is possible that the “true” compressive strength of the wallettes was lower than the  
 335 cylindrical specimens. To reassess the role of cohesion on the bearing capacity of RE walls under  
 336 concentrated loads, a numerical study was conducted, which will be presented in the following section.

#### 337 **4.4 Finite Element modeling**

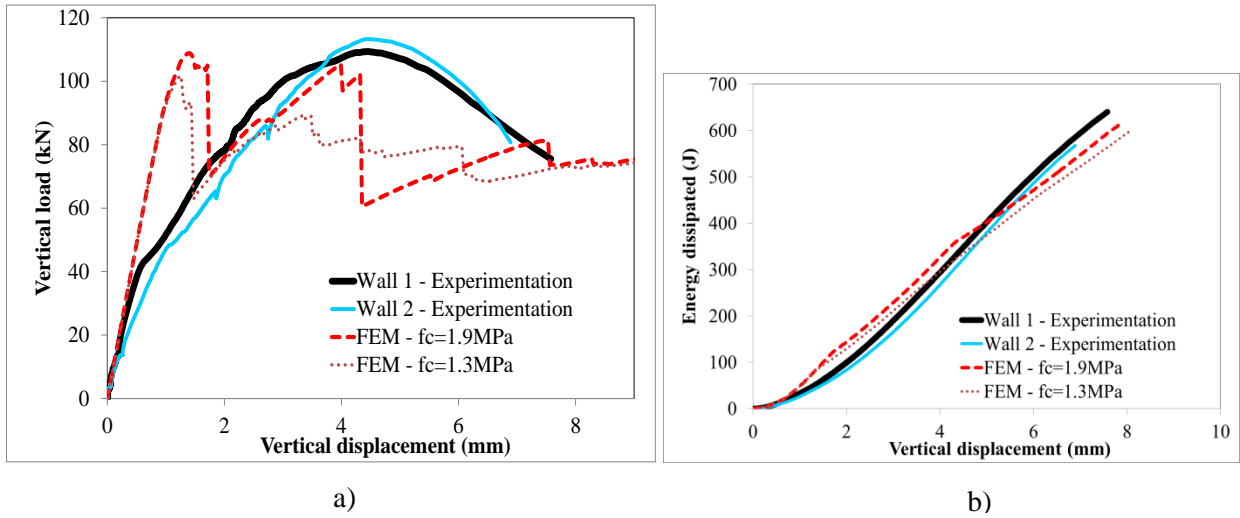

338 The wallettes were modeled using the advanced Finite Elements (FE) CASTEM code in which the complex  
 339 behaviors of materials were taken into account: nonlinearity, cracking and damage. The Mazars model  
 340 (Mazars 1986) was used. This is an isotropic nonlinear damage model and is frequently used for modeling  
 341 damage in concrete. This model is based on damage mechanics, so it can identify the decrease in stiffness  
 342 caused by the appearance of micro-cracks in the material. It is based on the scalar internal variable  $D$ , which  
 343 describes the damage in tensile or compressive loadings (Lemaitre 1996). The progression of damage is  
 344 distinguished by the sign of solicitation and is modeled by two scalar internal variables in tensile ( $D_t$ ) and  
 345 compressive damage ( $D_c$ ).

346 In the model, the wallette was considered homogenous and isotropic. This hypothesis was proved acceptable  
 347 in a previous study (Bui *et al.* 2009b). The modeling was in 2D (plane stress). The QUA4 elements (20 mm  
 348  $\times$  20 mm) with four Gaussian points were used. The Young modulus and the Poisson’s ratio were 500 MPa  
 349 and 0.22, respectively, according to experimental results on cylindrical specimens. Two models were tested:  
 350 in the first, a compressive strength of 1.9 MPa was used and in the second a compressive strength of 1.3 MPa  
 351 was used. Shear strength of 0.18 MPa was used for both models.

352 The numerical and experimental results are compared in Fig. 12. The initial stiffness obtained by the FE  
 353 model was identical to the experimental result (Fig. 12a); this shows that the Young modulus used was  
 354 correct. The numerical model could not reproduce the second phase of the walls’ behavior when the cracking  
 355 began and the stiffness decreased; this shows the limit of the used damage model. Indeed the Mazars model

356 is well known that it can reproduce the maximal load (by reproducing the damage energy) but it can not  
 357 reproduce the form of the behavior curve. Fig. 12b presents the evolution of dissipated energies that shows  
 358 that the numerical model captured well the damage energy (at 4.5-mm vertical displacement).

359  
 360  
 361  
 362

**Figure 12 Comparison of the numerical and experimental results.**

363  
 364  
 365

**Figure 13: Horizontal strains  $\epsilon_{xx}$  in the numerical model (at a 9mm vertical displacement).**

366 The failure modes of the numerical model were also similar to the experimentation (Figure 13): firstly, the  
 367 central vertical cracks appeared and then the inclined cracks propagated to the bottom corners of the wallette.  
 368 The numerical maximal loads were 110 kN and 103 kN, respectively, for 1.9 and 1.3 MPa of compressive  
 369 strength. These numerical results were close to the experimental results: the difference did not exceed 10%.  
 370 In these models, the compressive strength was varied but the shear strength was not modified. The numerical  
 371 results show that the compressive strength was not a primary parameter in this case because a 50% increase

372 in compressive strength leads to only a 6% increase in the wallette's maximal load. The stress concentration  
373 played an important role in this case and therefore the shear strength was the most important parameter.

#### 374 4.5 Shear strength on deep beams

375 Ciancio and Robinson (2011) used the "strut-and-tie" method to model lintels in SREs reinforced by lower  
376 longitudinal metallic rods. The "strut-and-tie" method worked well on most of the lintels studied; however,  
377 there were four lintels whose their failure mode and strength the authors could not explain. Indeed, these  
378 lintels were cracked due to the stress concentration (Figure 14) that was shown in the present study. This  
379 section will check whether the criteria based on shear strength reproduces the experimental results in the  
380 Ciancio and Robinson study.

386 **Figure 14: Failure of the four lintels in the Ciancio and Robinson (2011) study**

387 In the Ciancio and Robinson (2011) study, there were three values of compressive strength:

- 388
- 389
- 390
- 391
- Tests on cylindrical specimens that were manufactured in the cylindrical molds (D 10 cm × H 20 cm),
  - Tests on cylindrical specimens (D 8 cm × H 16 cm), which were cored from the wallettes,
  - Values recalculated from the maximal load obtained after tests on the lintels.

392

393 Among these three values, the values of the specimens manufactured in the molds are often overestimated  
394 (Bui *et al.* 2009b, Ciancio and Gibbings 2012). On the other hand, the tests on cored specimens usually give  
395 underestimated results because the specimen's microstructure is changed due to coring (Bui *et al.* 2007,  
396 Ciancio and Gibbings 2012). The recalculated values were between these two cases and therefore appear to  
397 be the best estimate. It is interesting to note that for SREs, the failure angle can also vary from 0° to 20°  
398 relative to the vertical plane.

399 The results obtained by the cohesion criteria and the experimental results are compared in Table 3. The  
 400 differences are relatively small (up to 10% overestimation), which proves that the approach using cohesion  
 401 can explain the experimental results. In practice, the formula  $f_{sh} = 0.1f_c$  can be suggested.

402

403 **Table 3 Comparison between the experimental results obtained by Ciancio and Robinson (2011) and**  
 404 **the theoretical results obtained by the cohesion-based criterion.**

Beam	Specimens	$f_c$ (Mpa)	$f_{sh}$ (Mpa)	$P_{theo.}$ (kN)	$P_{exp.}$ (kN)	$P_{theo}/P_{exp}$

405

## 406 5 Conclusion and prospects

407 This paper contributes data for RE structures subjected to specific loads: seismic loads and concentrated  
 408 loads. For seismic loads, a series of experiments were conducted to determine the tensile strength of RE  
 409 material. A relationship between the tensile and the compressive strengths was identified ( $f_t=0.11f_c$ ). It was  
 410 surprising that the tensile strength at the layer's interfaces was similar to that within the layers, but this result  
 411 confirms that the isotropic hypothesis is acceptable for RE material.

412 Concerning the behavior of RE walls under concentrated loads, in addition to the compressive strength  
 413 criteria, this study suggests that the stress's concentration at the loaded zones should be taken into account.  
 414 Experiments were conducted on two wallettes subjected to concentrated loads, which demonstrated the  
 415 vertical failure surfaces due to the differential displacement between the loaded zone and its surrounding  
 416 unloaded zones. A criterion based on the material's cohesion was proposed to characterize these failure  
 417 surfaces. Cohesion was identified by Mohr-Coulomb theory. FE modeling, which took into account

418 nonlinearity and crack development, was used, which confirmed the above results. Then this shear strength-  
419 based criterion was applied to a study on SREs, with satisfactory results. The study showed also the limit of  
420 the used damage model in the case of RE walls. Further studies are in development to improve the existing  
421 model so that it reproduces better the post-elastic phase.

422 In practice, the tensile strength and the shear strength of RE should be taken equal to 10% of the compressive  
423 strength (before being devised by safety factors) because the Mohr-Coulomb criterion may be nonlinear for  
424 RE material. If the safety ratio is applied for the compressive strength (which is 1.5 in Eurocode 2), the shear  
425 strength will equal 6.7% of the design compressive strength that is similar to recommendations in the New  
426 Zealand Standards (1998) which is 7%. Further experiments on other soils should be conducted to validate  
427 the approach proposed.
