ABSTRACT: SiO₂ constitutes one of the most widely used dielectric materials in microelectronics, packaging and optical industries. Therefore, the development of new processes to deposit SiO₂ at low temperature and in an affordable and scalable way are desirable. In this work, we present a low-temperature, open-air process based on spatial atomic layer deposition (SALD) that yields high purity SiO₂ films at temperatures down to room temperature. The films were obtained by operating our SALD system in CVD mode (i.e. allowing precursor crosstalk), using an oxygen plasma in combination with Trivinylmethoxysilane (TVMS). TVMS is an appealing precursor since it is highly volatile, affordable and does not contain halogen elements, thus being very suitable for application in atmospheric-pressure spatial deposition systems. Conversely, water, oxygen, hydrogen peroxide or ozone did not show any reactivity with TVMS at temperatures up to 260 °C. Thus, when operating our system in ALD mode, no film could be obtained due to the lack of reactivity of the precursor with OH* surface groups. 3D printing was employed to fabricate custom heads integrating both the precursor injector and the atmospheric plasma generator. Our results show that compact, conformal, pinhole-free SiO₂ thin films can be deposited by our atmospheric plasma-enhanced spatial chemical vapor deposition (APE-SCVD) approach at low temperatures (RT – 180 °C) on different substrates, including silicon wafers, micro-glass slides, or even on polymeric substrates with a high growth rate up to 2 – 5 nm/min. The deposition rate increased when increasing the power applied to the plasma reactor but decreased when increasing the deposition temperature due to the faster decay of the metastable oxygen radical species. FTIR results showed no differences for films deposited with different plasma powers. Conversely, temperature had an effect on the ratio between the AS₁ and AS₂ bands. Even though the deposition of SiO₂ was carried out at low temperatures in the open air using a metalorganic precursor, no contamination from SiN_x or SiC_x was observed by FTIR and XPS measurements. Our results open the door to the low-temperature, fast printing of Si-based devices.

1. INTRODUCTION

Silicon dioxide (SiO₂) is used in various fields such as microelectronics, packaging, or optical communication due to its excellent physical properties including corrosion resistance, dielectric nature, optical transparency, hardness, gas and humidity barrier, etc.^{1–3} SiO₂ thin films can be obtained using various techniques, including chemical vapor deposition (CVD),^{4,5} plasma-enhanced chemical vapor deposition (PECVD),^{6–8} atomic layer deposition (ALD)^{9–11} and physical techniques such as thermal oxidation,¹² magnetron sputtering,¹³ among others. For most of the mentioned techniques, SiO₂ deposition is usually performed at low pressure in a vacuum-chamber, which has a substantial repercussion on the cost of scaling up to industrial applications. Developing alternative approaches for the open-air deposition of Si-

based thin films at low temperatures and with high throughput is therefore desirable.

Recently, Atmospheric pressure spatial ALD (AP-SALD) has become an appealing alternative to conventional ALD, in that it allows deposition of highly conformal and uniform films even in the open atmosphere and with ultrafast deposition rates (up to two orders of magnitude faster than standard ALD).^{14–16} In addition, AP-SALD can be easily scaled up to large surfaces, since no vacuum chamber is needed. As a result, AP-SALD has been widely applied to the deposition of functional materials for new generation photovoltaics,^{17–20} or for the encapsulation of flexible electronics.^{21–24} Similar to conventional ALD and CVD processes, plasma activation of SALD has been already demonstrated by using atmospheric pressure plasmas.^{25,26}

In open-air SALD approaches, a gas manifold injector is used and placed very close to the substrate to avoid crosstalk of precursors across the inert gas barriers.^{27,28} The deposition area is thus only related to the size of the gas injector and its scanning amplitude over the substrate. While such approach was designed to perform ALD, the distance between the substrate and the injector (deposition gap) can be increased to facilitate the crosstalk of precursors in the gas phase, resulting in film deposition via CVD mode.²⁸⁻³⁰ This so-called spatial chemical vapor deposition (SCVD) mode allows depositing films with higher growth rates as compared to SALD while still retaining the main advantages of the latter, i.e. operating at low temperatures and in open air, as well as film quality and conformality inherent to ALD.²⁸ Furthermore, similar atmospheric plasma generators used in spatial reactors could also be used in SCVD mode, thus allowing more flexibility in processing conditions, such as a low deposition temperatures (< 100 °C) or a wider choice of precursors. The combination of atmospheric plasma generator and the SCVD technique would therefore be particularly beneficial to industrial-scale applications, such as for instance deposition of thin films for solar cells, barrier coatings, or layers for electronic device encapsulation.^{31,32}

So far, the most used precursors for the chemical vapor deposition of SiO₂ thin films are silane (SiH₄) and halogen-containing precursors, such as SiCl₄^{33,34}, Si₂Cl₆³⁵ or SiH₂Cl₂³⁶ because of their ability to provide high-purity films. The fabrication of SiO₂ films using these conventional precursors is often carried out at relatively high temperatures (> 400 °C). A manner to reduce the deposition temperature is to employ catalysts such as NH₃ or pyridine.^{37,38} Although the halogen-containing precursors are highly volatile and reactive, they are also pyrophoric and their use in SiO₂ fabrication produces corrosive gases. When considering the safety, toxicity, and compatibility with open-air low-cost chemical vapor deposition approaches, halide-free metalorganic precursors such as tetraethoxysilane (TEOS),^{5,6,39-42} tetramethylsilane (TMS)^{43,44}, di-isopropylaminosilane (DIPAS)^{45,46} or tris(dimethylamino)silane (TDMAS)⁴⁷ are indeed more attractive choices. Another potential candidate is trivinylmethoxysilane (TVMS) because of its high vapor pressure, non-toxicity and appealing cost. These qualities make TVMS very appealing in particular for use in atmospheric-pressure chemical vapor deposition systems. However, Burton *et al.* have demonstrated that this precursor is indeed not suitable for ALD due to its low reactivity towards SiOH* surfaces, as well as H₂O in the range of temperatures up to 400 °C.⁴⁷ Moreover, although a recent theoretical study by Vajeeston *et al.* indicates that TVMS should be a suitable candidate for the deposition of Si by ALD, to the best of our knowledge, this precursor has never been successfully used for both SiO₂ and Si thin film deposition via chemical vapor deposition techniques.

In this work, we have used an atmospheric plasma-enhanced spatial chemical vapor deposition (APE-SCVD) approach to deposit SiO₂ thin films at low temperatures (RT – 180 °C) in open air with high deposition rates (2 – 5 nm/min), on different substrates including glass slides, silicon wafers or flexible polymeric substrates. We have used a custom-designed and 3D printed one-block gas injection

head incorporating the atmospheric plasma generator. In such a configuration, a confined reaction zone is obtained, limited to the volume where the different precursors can meet over the substrate surface. This mixing zone is considered as a virtual CVD chamber whose volume can be easily controlled by modifying the injector-substrate gap. This enables more flexibility in controlling the growth rate, the roughness as well as the density of the deposited films. Trivinylmethoxysilane (TVMS) has been successfully used for the first time as a silicon precursor to deposit SiO₂ thin films with oxygen plasma as a co-reactant. The effect of different parameters on the SiO₂ film quality, including substrate temperature, oxygen plasma power, the gap between the substrate and the injection head, as well as the influence of the head design on the film quality is presented and discussed. Our work demonstrates that the spatial separation concept can also be applied to CVD reactors even when using plasma activation.

2. EXPERIMENTS AND PROCEDURE

Thin film deposition

Different depositions were performed in a home-build APE-SALD system equipped with a close-proximity manifold head. As described previously, by adjusting different parameters, the system can operate in a CVD mode,³⁰ while still showing a constant growth per cycle (GPC) and a high conformality.²⁹ Trivinylmethoxysilane (Si(C₂H₃)₃(OCH₃), TVMS, used as received from Fluorochem) was used as the silicon precursor, while oxygen plasma was employed as the oxidizing agent. The latter was produced using a home-built dielectric barrier discharge (DBD) plasma source, which contains two interdigitated copper grids and a fused quartz layer of 2 mm-thick in between as dielectric barrier.⁴⁸ The DBD source was integrated in a custom-designed deposition head that was fabricated by 3D printing using a Formlabs II 3D printer. The precursor bubbler was kept at room temperature. TVMS was delivered to the substrate by bubbling a 50 sccm nitrogen gas flow through the liquid precursor, which was then diluted with an extra nitrogen flow (100 sccm) before being sent to the injection head. The oxygen plasma was generated by delivering 200 sccm of pure oxygen to the DBD plasma source. The maximum voltage and frequency that can be applied to the DBD are 12 kV and 10 kHz, respectively. The silicon substrates and micro-glass slides used in this work were cleaned using ethanol, deionized water, and then dried under pure nitrogen. On samples used for TVMS surface reactivity tests, an extra 2 min long oxygen plasma cleaning for 2 min was employed to functionalize the substrate surface before exposing it to TVMS.

Characterization

The oxygen plasma was characterized by using a high-resolution optical emission spectroscopy (OES) system (SpectraPro HRS 750 from Princeton Instruments). The spectrum was obtained (in the dark) by pointing an optical fiber toward the DBD plasma source while oxygen was being injected.

The chemical composition of the deposited films was analysed by using Fourier Transform Infrared spectroscopy

(FTIR, Bruker VERTEX 70v) and X-ray Photoelectron Spectroscopy (XPS). XPS measurements were performed at BM25-SpLine laboratory using a standard ultra-high vacuum chamber with a pressure of 1×10^{-10} mbar. A hemispherical analyzer equipped with a channel-plate and a non-monochromatic Mg X-ray source ($h\nu = 1254.6$ eV) were used for the measurements. The energy scale was calibrated with the C1s line from contamination carbon at 284.8 eV. Analyses were carried out at a constant angle of 90° between the sample surface and the analyzer. The thickness, surface morphology, and mass density of deposited films were analyzed by ellipsometry (Film Sense FS-1), X-ray reflectometry (D500 Siemens, using Cu $K\alpha$ radiation ($\lambda = 0.15406$ nm), $0.01^\circ/\text{step}$, 2 s/step) and field emission gun-scanning electron microscopy (FEG-SEM Environmental FEI Quanta 250).

Simulation

A combination of three modules from Comsol Multiphysics was used for 2D simulation: heat transfer in fluids, laminar flow and transport of diluted species. The gas injector/substrate distance and the gas flow per outlet were kept at 150 or 500 μm and 100 sccm, respectively.

3. RESULTS AND DISCUSSION

As a first step, the reactivity of TVMS precursor with respect to different oxidizing agents and various substrates was investigated. As stated above, Vajeeston *et al.*⁴⁹ have used state-of-the-art density-functional calculations to predict that TVMS should be a suitable precursor for the ALD growth of Si and SiO_2 thin films because of a favorable surface adsorption on an $-\text{OH}^*$ terminated surface, and reaction of the precursor with itself in the case of Si deposition.⁴⁹ However, to our best knowledge, there are no reports in which TVMS has been successfully used to deposit SiO_2 or Si thin films by CVD or ALD techniques. In addition, Burton *et al.*⁴⁷ have used a conventional ALD reactor and FTIR to experimentally demonstrate that $\text{Si}-\text{OCH}_3$ bonds are relatively inert towards $\text{Si}-\text{OH}^*$ surface groups, while breaking $\text{Si}-\text{C}$ bonds to form $\text{Si}-\text{O}$ bonds may have an activation barrier that is kinetically limiting.

Thus, the ALD reactivity of TVMS with micro-glass slides, silicon substrates or oxygen plasma-treated silicon substrates has been tested, as well as its reactivity

Figure 1. a) 3D schematic view of the APE-SCVD injection head (inset: a photograph of the 3D printed APE-SCVD head used in this work); b) a 2D simulation obtained by Comsol Multiphysics, showing the mixture of TVMS and Oxygen plasma in the gas phase just above the substrate. The substrate/injector gap was maintained at $500 \mu\text{m}$ in this simulation,³⁰ and the color bar corresponds to the zone where both TVMS and atomic oxygen are present; c) Variation of SiO_2 film thickness as a function of high voltage applied to the DBD plasma source; d) Intensity variation of the oxygen atomic desexcitation peaks at 777 nm for different applied high voltages ranging from 7.8 kV to 9.5 kV; e) FTIR spectra of a 45 nm thick SiO_2 film deposited on a silicon substrate by APE-SCVD at 75°C ; f) Si 2p core level XPS spectrum of 45 nm thick APE-SCVD SiO_2 film deposited at 75°C .

with various oxidizing agents. Firstly, the surface adsorption activity of TVMS was tested by exposing it to micro-glass slides and two different silicon substrates (with and without extra plasma treatment, see experimental details) for 15 min at 100 °C, using our SALD system. More details related to the reactivity tests using a standard SALD injection head can be found in the SI, Figure S2. If TVMS adsorption on these surfaces takes place, one would expect the surface to be terminated by hydrophobic groups, i.e. $-C_2H_3$ since the dissociation enthalpy of the $SiO-CH_3$ bond at 298 K (358 kJ/mol)⁵⁰ is much lower as compared to that of the $Si-C_2H_3$ bond (527 kJ/mol).⁵¹ However, no difference in wettability of the substrates could be observed before and after exposure to TVMS. In addition, FTIR measurements (in the case of Si substrates) didn't show any trace of TVMS on the substrate surface, even for plasma treated substrates which contain a high density of $-OH^*$ groups (see more details in the SI, Figure S1). This indicates that no TVMS adsorption happened under the test conditions, thus implying that TVMS is not a suitable ALD precursor, at least when working at atmospheric pressure.

As detailed above, our spatial system provides the possibility of intermixing precursor and co-reactant in the gas phase above the substrate surface by adjusting the gap between the head and the substrate (a scheme of a standard SALD head used in our system is shown in Figure S2 in the SI). Thus, we explored the use of conventional oxidizers, namely H_2O , H_2O_2 and ozone, to test whether a SCVD growth mode leading to silicon dioxide deposition could be obtained using TVMS. In this case, no film growth was observed neither on glass nor on both standard and plasma-treated silicon substrates, thus confirming again the limited reactivity of TVMS against these co-reactants at atmospheric pressure and low temperatures (< 260 °C). In view of these results, the use of plasma assistance was explored, since a variety of highly reactive radicals are formed, among which atomic oxygen (O^*) can be used as an efficient oxidizing agent to react with TVMS. Figure 1a shows a 3D schematic drawing of the APE-SCVD reactor used, which was fabricated by 3D printing (see inset). Taking advantage of the possibilities offered by 3D printing, we could design both the oxygen plasma generator and the TVMS gas delivering outlet in a single one-block head. Figure 1b illustrates the result of a 2D simulation performed using Comsol Multiphysics (see more details in part 4 of the SI). It shows the mixture of TVMS and oxygen plasma in the gas phase above the substrate surface as a result of an increased deposition

gap of 500 μm (an oscillation speed of approximately 3 cm/s was considered). The colored zone shown in Figure 1b represents the concentration of the TVMS/oxygen plasma mixture in the gas phase at room temperature. The so-called CVD reaction zone corresponding to the volume of mixture can actually be simply monitored by adjusting the injection head-substrate gap. Similar to SALD, the thin film deposition is then obtained by exposing this CVD reaction zone to the substrate that moves underneath the precursor injector.

Figure 1c shows a tremendous increase in SiO_2 film thickness from 22 nm to 152 nm (for the same deposition duration) when the high voltage applied to the DBD varies from 7.75 kV to 10 kV, while all other experimental parameters such as carrier gas flow of TVMS (100 sccm), substrate temperature (180 °C) or the substrate/gas injector gap (150 μm) are maintained constant. This can be taken as an indication that the film growth rate is proportional to the concentration of atomic oxygen generated. This assertion is supported by OES measurements shown in Figure 1d, in which an increase in the intensity of the atomic oxygen characteristic triplet (777.19 nm, 777.42 nm and 777.54 nm)⁵² with the applied high voltage is clearly observed. It should be also noted that, even though the oxygen plasma is generated in open-air conditions, no emission from nitrogen species were observed in the plasma when pure oxygen was flown through the DBD (200 sccm). This proves that the DBD integrated 3D printing gas injector used in this work is very efficient to prevent nitrogen contamination in the plasma (further details can be found in Figure S3a in the SI). Consistently, FTIR and XPS spectra of a 45 nm thick SiO_2 sample (grown by APE-SCVD at 75 °C using 10 kV and 8 kHz for plasma generation) do not show any trace of silicon nitride or carbide, as shown in Figure 1e-f. Si-O-Si peaks only can be detected, which are located at 1062 and 1130 cm^{-1} in the FTIR spectrum, and at 103.4 eV in the XPS one (Si_{2p} peaks are located in the 900-950 cm^{-1} FTIR spectral region, and at 101.8 eV in XPS spectra,⁵³ while SiC_x peaks are at about 760 cm^{-1} and 100.5 eV, respectively, in FTIR and XPS spectra).⁵⁴ This remarkable observation demonstrates the possibility of using APE-SCVD and TVMS as silicon precursor to produce SiO_2 at low temperature in ambient condition, leading to thin films with low carbon and nitrogen contaminations. In view of this result, it is expected that the deposition of nitride films such as SiN_x could be achieved using open-air spatial approaches with a nitrogen DBD plasma.

Figure 2. Three designs of APE-SCVD head with various distances between the oxygen plasma and TVMS output channel: 2 mm (left), 6 mm (middle) and 12 mm (right). An exhaust channel was added to the 3rd case to further reduce the CVD mixture volume.

In the plasma activated spatial CVD mode used here, a separation effect between the precursor and plasma outlets should be expected, given that plasma species have a short lifetime. Figure 2 shows three schematic designs of 3 different deposition heads with varying distance values between the oxygen plasma and the TVMS (2 mm, 6 mm and 12 mm) output channels. In the third one, an exhaust channel was also present between the TVMS and plasma outlets, as is the case in typical SALD heads.

Figure 3. XRR patterns of SiO₂ samples prepared by APE-SCVD at 75 °C using different designs. The distance between the head and the substrate was maintained at 150 µm.

Figure 3 shows the XRR patterns of SiO₂ films deposited under identical conditions of gas flows and temperature (75 °C) using these different heads. Using the first two heads results in thin films with rather similar thickness, 47.4 ± 0.5 nm and 38.5 ± 0.5 nm, respectively. Despite yielding the thickest films, the first head design leads to rough films (0.40 ± 0.25 nm of roughness), as indicated by the absence of oscillation in the pattern. This can be explained by the fact that the concentration of oxygen atoms right at the two outlets is high, with the TVMS outlet located right next to them, making the CVD reaction very efficient. The second head design yielded films with a smoother surface (0.17 ± 0.1 nm of roughness), as indicated by the clear oscillations in the XRR pattern. Finally, the third design with a large distance between the TMVS and the oxygen plasma outlets, along with the addition of an exhaust channel, resulted in very thin SiO₂ film (5 ± 0.2 nm). This can actually be explained by the fact that the concentration of atomic oxygen decreases when travelling from the oxygen plasma outlets to the TMVS one. For this work, only the samples shown in the part concerning the effect of DBD voltage were deposited using the first injector design, while all other samples were deposited using the second one. In conventional CVD, a higher deposition temperature usually leads to a higher growth rate due to a more efficient decomposition of CVD precursors. However, in our case the film thickness significantly decreases when slightly increasing the deposition temperature (see Figure 4). Indeed, the decay processes of atomic oxygen such as $O + O + N_2 \rightarrow O_2 + N_2$ or $O + O + \text{surface} \rightarrow O_2$ are temperature-dependent. The relationship between

Figure 4. SiO₂ film thickness as a function of deposition temperature. In this experiment, the values of plasma frequency, high voltage and deposition duration were 8 kHz, 10 kV and 5 min, respectively. The inset image is a Comsol Multiphysics simulation of the temperature variation in the gas channel, the substrate temperature was fixed at 100 °C.

the recombination coefficient for oxygen atoms and substrate temperature has been experimentally addressed in several works, for instance Greaves & Linnette,⁵⁵ and Brovikova.⁵⁶ In these studies, an increase of the recombination coefficient for oxygen atoms was observed when the surface temperature varies from 20 °C to 150 °C. Therefore, a higher substrate temperature would lead to a decrease in the oxygen atom concentration, which agrees with the temperature-dependent growth rate of SiO₂ films observed in our case.

In addition to the growth rate, the substrate temperature also has an impact on the chemical composition of the deposited films. Figure 5a shows FTIR spectra of SiO₂ films deposited with our APE-SCVD system at different substrate temperatures, varying from RT to 150 °C. Figure 5b shows a normalized close-up of these spectra from 720 cm⁻¹ to 1600 cm⁻¹. Carbon contamination is usually found in SiO₂ films prepared by CVD techniques, mainly originating from the organic nature of CVD precursors and uncompleted chemical reactions leading to SiO₂ film formation.^{57–59} But in our case, it is remarkable that neither Si-CH_x nor Si-N groups are observed, even at deposition temperatures as low as RT and in open-air conditions. This means that all carbon species are efficiently removed during the APE-SCVD process thanks to the high reactivity of the close-proximity oxygen plasma. For the film deposited at RT, small C-H and C=O peaks are observed, which can be attributed to residues of TVMS or by-products from the reaction between atomic oxygen and TVMS. Moreover, when deposition is performed at low temperatures, Si-OH group formation and water absorption from the atmosphere may also increase the intensity of Si-OH and H-OH peaks located at wavenumbers around 928 cm⁻¹ and 3400 cm⁻¹. While temperature clearly affects the quality of the deposited films, the plasma power

had no sensible effect on FTIR spectra (see more details in Figure S3c-d of the SI).

Figure 5. a) FTIR spectra of SiO₂ samples prepared at various substrate temperatures, b-c) a zoom into the main Si-O peaks of the normalized spectra shown in Figure 5a, and an example of fitting the main peaks with different components: Si-O-Si transverse optical asymmetric stretch with adjacent O atoms in phase (AS₁), and with adjacent O atoms out of phase (AS₂), d) comparison of the AS₂/AS₁ ratio of APE-SCVD samples with SiO₂ samples prepared by other techniques.^{60,41} SiCl₄ was used for SiO₂ deposition by PECVD and Flame Hydrolysis Deposition.

A closer analysis in the [720 cm⁻¹, 1600 cm⁻¹] region containing the main Si-O-Si peaks is shown in Figure 5b and Figure 5c. The Si-O-Si transverse optical asymmetric stretch with adjacent O atoms in phase and with adjacent O atoms out of phase generates the two main peaks AS₁ and AS₂, respectively. The ratio of these peaks can be used as an index of the density and stoichiometry of the SiO₂ films. Indeed, a lower AS₂/AS₁ ratio corresponds to a higher quality of SiO₂ films (denser and stoichiometry closer to 1:2). Figure 5d shows a comparison of the ratio of our APE-SCVD samples deposited at various substrate temperatures with the ratios calculated for samples prepared by other techniques.^{60,41} Firstly, the AS₂/AS₁ ratio decreases from 0.56 to 0.31 when the deposition temperature increases from RT to 150 °C.

The value of the AS₂/AS₁ ratio of thermal SiO₂ is 0.16, while it is estimated to be about 0.35, 0.33 for samples prepared by PECVD,⁶⁰ and flame hydrolysis deposition⁴¹ using SiCl₄ at relatively high temperatures (250 °C – 700 °C), and 0.31 for sample deposited by APE-SCVD at 150 °C. Thus, our films have a quality that is comparable to films deposited by CVD at similar temperatures, or by flame hydrolysis at 700 °C. It should also be noted that the quality of as-deposited SiO₂ films by APE-SCVD can be further improved by a simple thermal annealing at 300 – 400 °C (see more details in Figure S4 of the SI).

One of the main advantages of the SCVD concept is the ability of localizing the CVD reaction zone, i.e. the mixture volume between metalorganic precursor and oxidizing agent. As previously shown in Figure 1b, this CVD reaction zone is

Figure 6. a) and b): simulation images of the CVD reaction zone obtained from 2D Comsol Multiphysics for two values of the injector/substrate gap (150 μm and 500 μm), the color intensity indicates the concentration of TVMS and atomic oxygen co-existing in the gap; c) and d): SEM micrographs of SiO_2 thin film deposited on glass substrates using two values of the gap, 150 μm and 500 μm , respectively. Samples were prepared at 50 $^\circ\text{C}$; e) and f) SEM micrographs of SiO_2 thin coating deposited on patterned silicon substrates using two values of the gap, 150 μm and 500 μm , respectively. Samples were prepared at 75 $^\circ\text{C}$.

indeed a small area localized within the gap between the gas injector and the heated substrate. Thanks to an appropriate design of the gas injector, and by a careful adjustment of the distance between the injector and the substrate, as well as the other deposition parameters, the size of this ‘virtual CVD chamber’ can be easily monitored. Figure 6a and Figure 6b show simulation images of the CVD reaction zone obtained using 2D Comsol Multiphysics for two values of injector-substrate gaps of 150 μm and 500 μm , respectively. As can be observed, the mixture volume of TVMS and atomic oxygen is clearly larger and more efficient, as evidenced by a deeper color intensity, at larger substrate-injector gap (500 μm), which means that for a constant precursor concentration at the inlet, a higher TVMS-to- SiO_2 conversion efficiency should be found. Interestingly, SEM micrographs of SiO_2 deposited on glass substrates using these two gap values show a clear difference in the deposited film thickness, i.e. 145 nm versus 290 nm, as shown in Figure 6c and Figure 6d. In contrast, although the higher gap value roughly yields twice as large as growth per cycle, the obtained films are rather rough with visible co-deposited particles. A similar situation was also observed when high-aspect-ratio features, such as patterned silicon substrates, were coated with SiO_2 thin layers, as shown in Figure 6e and Figure 6f. Accordingly, using the higher substrate-injector gap, i.e. 500 μm , yields a 87 nm-thick coating layer, along with the presence of particles, while using the closer gap allows depositing a highly conformal, 45 nm-thick layer without any visible co-deposited nanoparticles. In both cases, the deposition is highly conformal. This result can be attributed to the large vertical

distribution of the TVMS/atomic oxygen mixture in the case of larger gap, which leads to nanoparticle formation in the gas phase that may then be deposited over the thin film. For this reason, a thinner CVD mixture zone, or in other words, a smaller gap between the gas injector and the substrate, should generate a better film quality. Nevertheless, one can adjust the deposition parameters in the APE-SCVD system as a function of the targeted application, to produce high-quality, smooth films or higher coating rates when roughness is not an issue.

4. Conclusion

In summary, we have demonstrated in this work the possibility of growing SiO_2 thin films at low temperatures (RT – 180 $^\circ\text{C}$), in open-air conditions using the atmospheric plasma-enhanced spatial chemical vapor deposition (APE-SCVD) technique. Taking advantage of the 3D printing technology, both precursor injector and the plasma generator were integrated into a single head, which is then placed at very close distance (150 – 500 μm) to the substrate. This provides a very efficient supply of highly reactive chemical species (atomic oxygen in this case) to activate the CVD reaction on the substrate surface. We have shown that SiO_2 deposition is not possible at temperatures up to 260 $^\circ\text{C}$ using TVMS as silicon precursor and H_2O , H_2O_2 or O_3 as co-reactant. However, SiO_2 deposition was successful when combining TVMS with an oxygen plasma containing highly reactive atomic oxygen. Our experimental results show that

compact, conformal, **pinhole-free** SiO₂ thin films can be deposited with a high growth rate of 2 up to 5 nm/min on different substrates including silicon, glass and polymeric substrates. The APE-SCVD technique leads to SiO₂ thin films with non-detectable SiN_x or SiC_x contamination levels, as confirmed by XPS or FTIR measurements, despite the use of a metalorganic precursor and low processing temperatures. Our findings open up a new approach for the deposition of functional thin films with a larger choice of available precursors and lower input thermal energy budget.

ACKNOWLEDGMENT

This work was funded by the Agence Nationale de Recherche (ANR, France) via the programs ANR-16-CE05-0021 (DESPATCH), ANR-17-CE05-0034 (OXYGENE), and the “Investissements d’avenir” program (ANR-15-IDEX-02) through the project Eco-SESA. D.M.-R. also acknowledges support from the European Union’s Horizon 2020 FETOPEN-1-2016-2017 research and innovation program under grant agreement 801464. Funding from the University Grenoble Alpes is acknowledged through the AGIR POLE 2016 program under the grant SURPASS. This work was benefited from funding from the Consejo Nacional de Ciencia y Tecnología (CONACYT) from Mexico (No. 456558). The authors acknowledge the Consortium des Moyens Technologiques Communs (CMTC)—Grenoble INP platform—for the characterization equipment.
