Integrated multi-criteria velocity and semi-active suspension control based on look-ahead road information

Hakan Basargan, András Mihály, Péter Gáspár and Olivier Sename

Abstract—Semi-active suspension control and vehicle cruise control systems have already been developed by researchers and adapted by automotive companies. Most of these systems react on actual road irregularities and terrain characteristics, and the control for each subsystem is designed separately. However, since oncoming road conditions can be known by using historic road information and GPS navigation system, the paper introduces a method to build in look-ahead road data in the control of the adaptive semi-active suspension, moreover, design the vehicle velocity for the cruise controller considering comfort and energy efficiency at the same time. The operation of the presented integrated suspension and velocity control system is validated by a real data simulation in TruckSim environment.

I. INTRODUCTION

Recently, vehicle technologies have been majorly studied in both academic and industry while vehicle suspension systems are an important research topic with significant developments in the last decades. Vehicle suspension systems can be classified in three categories, which are passive, semi-active, and active depending on the operation mode. The goal of the semi-active and active suspension is to improve vehicle safety and ride comfort, through minimizing the effects of road disturbances. Passive suspension is still commonly used, but it is limited in improving ride comfort or suspension deflection [1]. Semi-active suspension systems apply variable damping characteristics expressing a significant improvement over passive suspension systems. Semi-active suspension systems can be adjusted to provide better suspension by absorbing energy, while they cannot forward energy to the system as an active suspension.

There are numerous publications related to design of semi-active suspension control ([2],[3],[4],[5]) which are safety-oriented problems ([6], [7]) and comfort-oriented problems([8], [9]), while most of them don't consider velocity design and several road distortions. This study proposes

The research was supported by the National Research, Development and Innovation Office through the project 'Integration of velocity and suspension control to enhance automated driving comfort in road vehicles' (NKFIH 2018-2.1.13-TÉT-FR)

a method to build in look-ahead road data in the control of the adaptive semi-active suspension, and besides, design the vehicle velocity for the cruise controller considering comfort and energy efficiency at the same time. The operation of the introduced integrated velocity and suspension control system is validated by a real data simulation in TruckSim environment.

The paper is organized as follows: Section II mentions energy efficient cruise control. Section III presents the control-oriented quarter-car model and the LPV controller synthesis. Section IV describes integration of the system and the method of defining the scheduling variable ρ based on the look-ahead estimation algorithm. Section V demonstrates the operation of the proposed method in high-fidelity TruckSim simulation environment with real road data. Finally, concluding remarks are presented in Section VI.

II. ENERGY EFFICIENT CRUISE CONTROL

The look-ahead control algorithm has already been introduced in [10], hence here only a brief explanation is given. First, the selected look-ahead distance L is split into n number of road sections, see Fig. 1.

Fig. 1. Segmentation of forward road

Assuming slope angles and speed limits to be known for every road section endpoints, the following formula is given to calculate the optimal velocity:

$$\vartheta = \sqrt{\vartheta - 2s_1(1 - Q)(\ddot{\xi}_0 + g \sin \alpha)}. \quad (1)$$

where

$$\vartheta = Qv_{ref,0}^2 + \sum_{i=1}^n \gamma_i v_{ref,i}^2 + \frac{2}{m} \sum_{i=1}^n (s_i F_{di,r} \sum_{j=i}^n \gamma_j). \quad (2)$$

where s_i , $i \in [1, n]$ is the road segment length with $L = \sum s_i$, $v_{ref,i}$ stands for the reference speed at every section endpoint, while $F_{di,r} = mg \sin \alpha_i$ is the road disturbance force at each section point originated from the slopes on the look-ahead distance.

In order to meet the desired goals, two optimization problem must be solved at the same time: both longitudinal control force and deviation from the speed limits must be minimized. The first criteria related to energy efficiency is realized by the minimization of longitudinal control force: $F_{l1}^2 \rightarrow \min$. Hence, a quadratic optimization problem is solved given as:

$$\bar{F}_{l1}^2 = (\beta_0(\bar{Q}) + \beta_1(\bar{Q})\bar{\gamma}_1 + \dots + \beta_n(\bar{Q})\bar{\gamma}_n)^2 \rightarrow \min \quad (3)$$

Next, deviations from the speed limits must also be minimized, which is formulated as follows:

$$|v_{ref,0} - \dot{\xi}_0| \rightarrow \min \quad (4)$$

Note, that optimal solution for this latter criterion is to choose $\bar{Q} = 1$ and $\bar{\gamma}_i = 0, i \in [1, n]$.

The convenient balance between the conflicting performances is set by introducing two further performance weight $0 \leq R_1 \leq 1$ and $0 \leq R_2 \leq 1$, with the constraint $R_1 + R_2 = 1$. Here, performance weight R_1 is related to the relevance of energy optimal operation of the look-ahead cruise controller, while R_2 is connected to the importance of minimizing the total travel time.

III. MODELING AND CONTROL SYNTHESIS OF THE SUSPENSION SYSTEM

Several researchers already developed active semi-active suspension systems based on the quarter-car model with very different approaches. Although linear quadratic and \mathcal{H}_∞ suspension control can guarantee good performance in both passenger comfort and stability, due to the fixed weighting of performances a dynamic control reconfiguration is not possible, see [11]. In [12] an approach using on-line road profile identification has been introduced, thus the semi-active suspension system had road adaptation capabilities. Here, the semi-active suspension control is founded on the Linear Parameter Varying (LPV) framework, as already introduced in see [13], [14].

The layout of the commonly used two-degree-of-freedom quarter-car model is shown in Figure 2. The dynamic model of the quarter-car semi-active suspension system and the actuator is written as follows:

$$m_s \ddot{q}_1 + b_s(\dot{q}_1 - \dot{q}_2) + k_s(q_1 - q_2) + F_{mr} = 0 \quad (5a)$$

$$m_u \ddot{q}_2 + b_s(\dot{q}_2 - \dot{q}_1) + k_s(q_2 - w) - F_{mr} = 0 \quad (5b)$$

where the actuator dynamics is approximated as

$$\dot{F}_{mr} = -\frac{1}{\tau} F_{mr} + \frac{1}{\tau} u. \quad (6)$$

Here, m_s is the sprung mass of the quarter vehicle, m_u represents the unsprung mass, k_t is the stiffness of the tire, k_s is the stiffness of the spring, b_s is the damping rate of the shock absorber, while F_{mr} is the control force generated by

Fig. 2. Quarter-car model

the actuator and $u = F$ is the control input of the system. Note, that q_1 and q_2 are the vertical displacement of the sprung mass and the unsprung mass, while road disturbance is denoted with w . The nominal parameters of the quarter-car model for the front and rear suspension is shown in Table I.

TABLE I
SUSPENSION PARAMETERS

Parameters (symbols)	Front suspension	Rear suspension	Unit
sprung mass (m_s)	214	336	kg
unsprung mass (m_u)	40	40	kg
suspension stiffness (k_s)	30	60	kN/m
tire stiffness (k_t)	220	220	kN/m
damping (b_s)	50	50	N/m/s
time constant (τ)	1/30	1/30	s

The unmodelled dynamics Δ are also taken into consideration with $|\Delta(\omega_1)| = 0.25$ at low frequencies and $|\Delta(\omega_2)| = 1$ at high frequencies, and is assumed to be stable with the norm condition $\|\Delta\|_\infty < 1$. The state vector x is selected as $x = [x_1 \ x_2 \ x_3 \ x_4 \ x_5]^T$, in which the components are the vertical displacement of the sprung mass $x_1 = q_1$, the vertical displacement of the unsprung mass $x_2 = q_2$, their derivatives $x_3 = \dot{q}_1$, $x_4 = \dot{q}_2$ and the control force $x_5 = F_{mr}$.

Next, performance specifications are defined in order to achieve a desired trade-off between ride comfort and road holding, while also taking control force into consideration. Hence, for the sake of increasing passenger comfort, the acceleration of the sprung mass must be minimized with the following optimization criterion: $z_1 = \ddot{q}_1 \rightarrow 0$. Directional stability is guaranteed with the minimization of suspension deflection, hence $z_2 = (q_1 - q_2) \rightarrow 0$. In order to reduce variations of side force to guarantee stability, the dynamic tire load must be minimized with the optimization criterion $z_3 = (q_2 - w) \rightarrow 0$. Finally, on order to avoid actuator saturation, the control force must also be considered with the optimization criterion $z_4 = F \rightarrow 0$. These performances are put in a performance vector $z = [z_1 \ z_2 \ z_3 \ z_4]^T$. The measured signal is the relative displacement between the masses, i.e $y = x_1 - x_2$. The control input u is the vertical force generated by the MR damper, with the dynamics listed in (6).

Next, the system given with (5) is transformed into state

space representation form as follows:

$$\dot{x} = Ax + B_1w + B_2u \quad (7a)$$

$$z = C_1x + D_{11}w + D_{12}u \quad (7b)$$

$$y = C_2x + D_{21}w + D_{22}u \quad (7c)$$

The proposed high-level controller is founded on a weighting strategy formulated through a closed-loop architecture shown in Figure 3.

Fig. 3. Closed-loop interconnection structure

Here, G is the quarter-car control oriented model defined in (7), K is the designed Linear Parameter Varying (LPV) controller characterized with the scheduling variable ρ responsible for control reconfiguration, u is the control input, y is the measured output, n is the measurement noise, z represents the performance outputs and w stands for the road disturbance.

The uncertainties of the quarter-car model is considered with weighting function W_r and Δ . Note, that weighting functions should be considered as penalty functions, hence weights should be large where small signals are desired and vice versa. The aim of weighting function W_n is to represent sensor noises, while weighting function W_w stands for the road disturbances. The goal of weighting functions given in W_p are to keep the sprung mass acceleration (W_{p_a}), suspension deflection (W_{p_d}), tire deflection (W_{p_t}) and control input (W_{p_u}) small over the required frequency range. Note, that while W_{p_a} represents passenger comfort, W_{p_d} and W_{p_t} stands for directional stability and dynamic tire load. Since the predefined performance specifications may conflict with each other, weighting functions given in W_p must be designed in a manner that an appropriate trade-off can be guaranteed between them. Moreover, in order to ensure control reconfiguration in case one of the predefined performances becomes more important due to estimated future road conditions, a scheduling variable $\rho \in [0.01, 0.99]$ is introduced to shape weighting function W_{p_a} , W_{p_d} and W_{p_t} . Hence, these performance weighting functions related to passenger comfort and road holding are selected in a second-order proportional form as follows:

$$W_{p_a} = \rho \frac{\alpha_1 s + 1}{T_1 s + 1} \quad (8a)$$

$$W_{p_d} = (1 - \rho) \frac{\alpha_2 s + 1}{T_2 s + 1} \quad (8b)$$

$$W_{p_t} = (1 - \rho) \frac{\alpha_2 s + 1}{T_2 s + 1}, \quad (8c)$$

where $\alpha_{1,2,3}$ and $T_{1,2,3}$ are designed parameters. Note, that weighting functions W_{p_a} , W_{p_u} , W_r , W_n and W_w are all given in similar linear and proportional form without containing the scheduling variable ρ .

The LPV performance problem is to choose a parameter-varying controller, which guarantees quadratic stability for the closed-loop system while the induced \mathcal{L}_2 norm from the disturbance ω to the performances z is smaller than the value γ , as described in [15], [16]. Hence, the minimization task is given as:

$$\inf_K \sup_{\rho \in \mathcal{F}_P} \sup_{\|w\|_2 \neq 0, w \in \mathcal{L}_2} \frac{\|z\|_2}{\|w\|_2} \leq \gamma. \quad (9)$$

The solution of an LPV problem is governed by the set of infinite dimensional LMIs being satisfied for all $\rho \in \mathcal{F}_P$, thus it is a convex problem. In practice, this problem is set up by gridding the parameter space and solving the set of LMIs that hold on the subset of \mathcal{F}_P , see [17].

The result of the presented design is a reconfigurable LPV controller, where $\rho = 1$ stands for a setup where passenger comfort is preferred, whereas $\rho = 0$ represents a controller focusing on stability and road holding of the vehicle. When ρ is between these edge values, a combination of performances are guaranteed by the controller.

Since the modeled MR damper has limitations on the control input force $u = F$, a semi-optimal solution is given as follows:

$$F = \begin{cases} F_{opt}, & \text{if } \dot{q}_1(\dot{q}_1 - \dot{q}_2) > 0 \\ 0, & \text{if } \dot{q}_1(\dot{q}_1 - \dot{q}_2) < 0 \end{cases} \quad (10)$$

where F_{opt} is optimal force, \dot{q}_1 is sprung mass velocity and $\dot{q}_1 - \dot{q}_2$ is deflection velocity.

IV. SYSTEM INTEGRATION AND DECISION LOGIC MODEL

The aim of this section is to describe system integration and the method of defining the scheduling variable ρ based on the look-ahead estimation algorithm. Figure 4 shows the integration of the longitudinal and vertical control system, where a decision logic selects compatible ρ based on the road data, previous measurements and the calculated optimal velocity λ given by the look-ahead method using GPS based road data. Latter also serves as input for the cruise control that calculates the longitudinal control force for the vehicle.

It is necessary to categorize the road to select the right ρ value according to different road types. The ISO 2631-1 standard characterize ride comfort based on the vibrations acting on the passengers [18]. Root mean square (RMS) of magnitudes of overall vibration is shown in Table II while the weighted RMS acceleration is expressed in terms of radians per second squared for rotational vibrations and defined in (11). ISO 2631-1 standard was considered to categorize the road with different distortion types, which can be seen in Table II.

$$a_w^{RMS} = \sqrt{\frac{1}{T} \int_0^T a^2(t) dt} \quad (11)$$

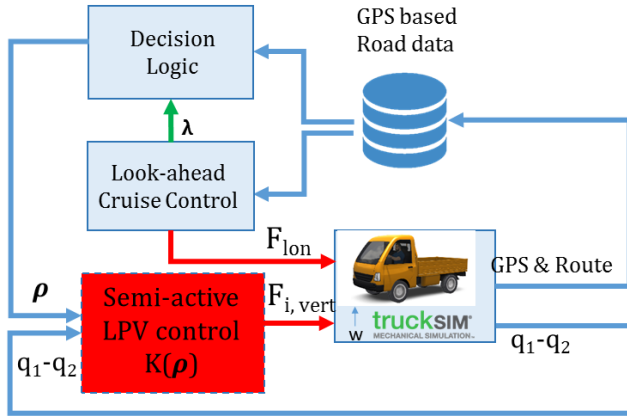

Fig. 4. Integration of the system

where $a(t)$ is the frequency-weighted acceleration time and T is a number of acceleration values.

TABLE II
MAGNITUDES OF OVERALL VIBRATION ACCORDING TO ISO
2631-1:1997

Frequency-weighted vibration magnitude (FWVM)	Likely reaction in public transport
Less than 0.315 m/s^2	Not uncomfortable
$0.315\text{-}0.63 \text{ m/s}^2$	A little uncomfortable
$0.5\text{-}1 \text{ m/s}^2$	Fairly uncomfortable
$0.8\text{-}1.6 \text{ m/s}^2$	Uncomfortable
$1.25\text{-}2.5 \text{ m/s}^2$	Very uncomfortable
Greater than 2 m/s^2	Extremely uncomfortable

TABLE III
ROAD TYPE, VIBRATION MAGNITUDE VALUE AND SELECTED ρ

Road Type	FWVM(m/s^2)	Road Category	ρ
Flat road	0.0043	Not uncomfortable	1
Road with roughness	0.026	Not uncomfortable	0
10 cm bump	0.116	Not uncomfortable	0
Multiple 5 cm dist.	0.370	A little uncomfortable	0.5
Sine sweep	0.431	A little uncomfortable	0.5

Selection of ρ algorithm considers a look-ahead estimation algorithm based on prehistoric simulations of passive suspension, which were performed to calculate FWVM and tire deformation RMS values with different road distortions and different velocities. These simulation results can be seen in Figure 5(a) and Figure 5(b). One of these results for 20 km/h with the road classification (road category) are shown in Table III. In Figure 5(b), It is possible to see that change in tire deformation and vertical acceleration of sine sweep road distortion is quite large due to its repetitive bumps and potholes distortions, thus multiple ρ can be defined for different velocities. The point where the FWVM values are lowest is when the velocity is between 20 km/h and 40 km/h and in the same way, in the range where the velocity

(a) FWVM values(RMS)

(b) Tire deformation of Front-Left wheel(RMS)

Fig. 5. Passive suspension simulation result of different road distortions

is 40-60 km/h , tire deformation is smallest. Thus, stability can be kept in consideration between 40-60 km/h while comfort can be preferred between 20-40 km/h .

According to Table III, the FWVM value of flat road is near-zero, thus comfort-oriented semi-active suspension approach can be considered by selecting $\rho = 1$ through there is not a safety-related problem. In the case of the "not uncomfortable" road category which is not near-zero, stability can be prioritized with $\rho = 0$ because the RMS value of vertical acceleration is not high. If the FWVM value is between $0.315\text{-}0.63 \text{ m/s}^2$ which is defined as "a little comfortable" road category, either tire deformation and vertical acceleration are quite high, therefore both comfort and stability can be considered with the same importance by selecting $\rho = 0.5$. This selected ρ can be seen in Figure 9(a) and Table III.

V. SIMULATION RESULTS

The simulation vehicle is a compact utility truck with independent front and rear suspension and half tonne of payload. A highway simulation route has been built in TruckSim environment based on real geographical and speed limit data, see Figure 6.

In order to demonstrate the effectiveness of the proposed method two different simulation has been performed and compared, one with the utility truck having conventional semi-active suspension and another with an adaptive semi-active suspension control. Note, that only a 3 kilometer section of the route has been considered, with the road

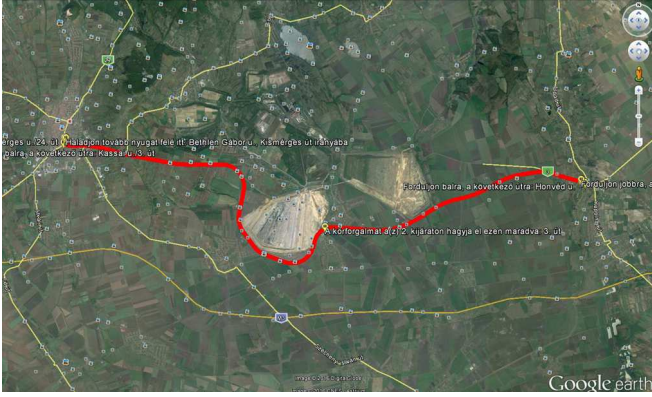

Fig. 6. Real data simulation route

geometry and roughness shown in Figure 7. As it can be observed in Figure 7(a), there are three major curves in the selected road section around 400 m, 1000 m and 1700 m. Moreover, there are also three different kind of road irregularities apart from the standard road roughness, as it is shown in Figure 7(b). First, around 100 m there is a left and right side bump following each other having 100 mm of height. This kind of road irregularity represents the effect of driving over a speed bump, which is common in urban areas. Next, after 1050 m there are bumps and potholes following each other differently for the left to the right side of the lane, having a height and depth of 50 mm. This road irregularity represents bad road quality with discontinuities in the asphalt. Finally, at 2000 m there is a longitudinal sinusoidal road irregularity with growing frequency, putting extreme stress on the suspension system of the simulated vehicle. This kind of road surface is typical at bus stops, where the frequent braking of heavy road vehicles roll up the asphalt.

(a) Road X-Y plane

(b) Road roughness

Fig. 7. Geometry and roughness of the road section

The speed limit varies on the route, and both vehicle calculates its corresponding optimal velocity based on the energy efficient look-ahead method, see Figure 8.

Fig. 8. Velocity of the simulated vehicles

The result of the look-ahead road consideration can be observed in Figure 9(a), where the scheduling variable ρ for the LPV controller is depicted. Focusing on road irregularities (100 m, 1050 m, 2000 m), the look-ahead based algorithm also selects a different value for ρ based on the decision logic. The actuated control forces for each quarter suspensions are depicted in Figure 9(b), having bigger values at the three main road irregularities.

(a) Scheduling variable ρ

(b) Suspension control forces

Fig. 9. Scheduling variable and actuated control force

The performances defined in Section III are compared for the two simulated vehicles. It is well demonstrated by comparing Figure 10(a) and Figure 10(b), that the amount of suspension deflection over the critical bumps have been decreased for the vehicle with the proposed adaptive suspension control system.

Also, tire deformation depicted in Figure 11(a) and Figure 11(b) has been slightly decreased with the proposed method.

Thus, it has been shown that both suspension deflection and tire deformation has been improved, resulting in better stability and road holding of the vehicle, while vertical acceleration has also been improved, especially at the sinusoidal road irregularity (see Figure 12).

VI. CONCLUSION

The paper proposed a novel integrated look-ahead semi-active suspension system, adapting the controller's perfor-

(a) Without adaptive control

Fig. 12. Vertical acceleration

mance to further road conditions and the vehicle velocity profile given by energy-efficient cruise control. The road quality information along with the velocity reference are both considered to define the corresponding scheduling variables for the adaptive semi-active suspension system. Hence, the

vehicle is able to adapt its suspension control system in coherence with oncoming road conditions and actual velocity, which improves both ride quality and stability of the vehicle. The control reconfiguration has been designed founded on the LPV framework, while the operation of the proposed method has been demonstrated in a real data simulation in the TruckSim environment.
